Abstract

In this work, a simple method for producing Perovskite solar cells [PSCs] by recycling automobile batteries is used. Trying to get rid of some structures or materials which are harm to the environment (i.e. recycled car batteries) by using lead [Pb] sheets from those battery. Also, by reusing car batteries we will avoid the disposal of toxic battery elements and provide an alternative technique, readily-available Pb source for fabricating PSCs. Perovskite solar cells [PSCs] were prepared by two-step spin coating solution method grown on the FTO glass substrate. The organo-halide PSCs consists of four layers over FTO glass substrate. Lead iodide (PbI₂) and methyl-ammonium iodide (CH₃NH₃I) used to form the structure of the precursor (CH₃NH₃PbI₃) by the above-mentioned coating method. The photovoltaic performance of PSCs was investigated, together with the stability of PSCs, and the effect of annealing temperature of PRK layer on performance of PSCs. Characterization of PSCs achieved by using X-ray diffraction, SEM, and Spectrophotometer techniques. The effect of annealing on the optical properties of MAPbI₃ films were studied by measuring spectral transmittance. The energy band gap value of the MAPbI₃ film was found to be 1.60 eV.

Keywords: perovskite solar cells, device fabrication, photocells, FTO substrate, X-ray diffraction

I. INTRODUCTION

The third-generation solar cells (PSCs) halide perovskite organic-inorganic solar cells have attracted a great deal of attention of solar cell research community due to an incredible device efficiency improvement from 3.8% to 22.1% since 2009 [1,2]. PSCs not only solve energy crisis, also reduce the emission of CO₂ causes the global warming and eradicating of toxic lead in old car batteries for serving solar energy. The perovskite materials have been demonstrated with largely tunable band gap (e.g., CH₃NH₃PbX₃ has a band gap from 1.5 eV to 2.3 eV) [3], with a high optical absorption coefficient (more than 10⁴ cm⁻¹) [4,5], similar to CdTe [6], copper zinc tin sulfide (CZTS) [7], and other thin film solar cells. It's a low-cost and convenient fabrication techniques as compared to silicon-based devices that require complicated and costly high-vacuum deposition methods. Reports of successful cell fabrication on flexible substrates even indicated a greater possibility to the large-scale roll-to-roll manufacturing of PSCs

that can be used in the industries [8–10]. The initial meaning of “perovskite” was about the crystal structure of calcium titanate, which was discovered in 1839 by the German mineralogist Gustav Rose and was named by the Russian mineralogist Lev Perovski. Since then, the term “perovskite” was referred to all compounds with the same crystal structure as calcium titanate. The perovskite light absorption layer has a general formula of ABX₃, where A is an organic cation (e.g., methyl-ammonium CH₃NH₃⁺), B is a metal cation (e.g., Pb²⁺) and X stands for the halide anion (e.g., I⁻). The perovskite materials have a general crystal structure described as ABX₃, where “A” and “B” are cations with varied sizes and “X” is an anion. A typical unit cell structure of a basic perovskite compound is shown in Figure 1. Organometallic halide perovskites include an organic cation (e.g., methyl-ammonium CH₃NH₃⁺, ethyl-ammonium CH₃CH₂NH₃⁺, formamidinium NH₂CH=NH₂⁺), a metal cation of carbon family (i.e., Ge²⁺, Sn²⁺, Pb²⁺) and a halogen anion (i.e., F⁻, Cl⁻, Br⁻, I⁻). Among them, methyl-ammonium-lead-iodide (MAPbI₃) is the most widely used perovskite light

absorber. Some recent research efforts also replaced lead with other metal ions due to the concern of toxicity of lead during device fabrication, especially for the future large-scale manufacturing [11,12]. In addition, several organic cations (CH_3NH_3^+ and $\text{NH}_2\text{CH}=\text{NH}_2^+$), inorganic cations (Cs^{2+} and Sn^{2+}) and halide anions (Br^- , Cl^- and I^-) have been used to improve the efficiency and stability.

Fig.1. Crystal structure of normal perovskite solar cells of the general formula ABX_3 [13].

The PRK has different structures which are temperature-dependent. When the temperature is below 100 K, the unit cell structure will have an orthorhombic phase. When the temperature rose to 160 K, the tetragonal phase (β) became visible and replaced the peculiar orthogonal phase (γ) [14]. With a further increase in temperature to about 330K, tetragonal to stable cubic (α) transformation will occur [15]. Figure 2. Shows three different phases.

Fig. 2. Comparison between (a) orthorhombic, (b) tetragonal and (c) cubic perovskite crystal structures [16].

II. METHODOLOGY

A. Sample Preparation

First disconnect the battery from the car (12 V, 799.7gm lead) with metallic harvester [17] with a metal cutter. The acidic electrolyte was carefully removed and collected, and the electrode, as well as the inner wall of the car battery, was washed several times with clean water. The electrolyte contains concentrated sulfuric acid (H_2SO_4). The resulting car battery was dried in ambient conditions for 3 days. The car's dry battery was removed from the top cover and then inspected from the sides to remove the electrode panels. After displacement, the material recovered from the lead is separated from the lead (anode) and the lead dioxide (cathode) are separated from the current collectors and diluted successively with HCl (hydrochloric acid) and wash with clean water. The collected material was ground

in powder for further synthesis. Lead dioxide (PbO_2) must be converted to lead oxide (PbO) using a ceramic crucible to roast lead dioxide (PbO_2) in a muffle furnace at 600°C for 5 hours. After heating Lead Dioxide at 600°C for 5 hours it has to be cooled at room temperature. During this process, the color of PbO_2 powder was changed from dark brown to yellow color (PbO powder). Preparation of Lead Iodide from Lead Acetate Dissolve 3 g of PbO (lead oxide) in 5 ml of acetic acid. Preparation of lead iodide from lead nitrate by constant stirring in a magnetic stirrer 3 g Pb in 5 ml of nitric acid and then dissolve 10 ml of potassium iodide, potassium iodide acts as a catalyst to increase the rate. Stirring the solutions for 30 minutes at 500 rpm using magnetic stirrer. Clean the solution by leaving the solution in aerobic position for 1 day, then using a centrifuge, the solution must be filled in centrifuge tubes, then deionized water is added to the solution, then centrifuged at 5000 rpm for 5 minutes to carry out the procedure. Repeat 3 times to completely remove the acid concentration, the precipitate will precipitate due to a change in density, and then the acid concentration must be removed. After centrifuging the solution, the solution has to be dried in aerobic condition during the entire procedure the solution has to be placed in a fume hood or fume cupboard. A fume hood or fume cupboard is a type of local ventilation device that is designed to limit exposure to hazardous or toxic fumes, vapors or dusts. Then, for preparation of methylammonium iodide ($\text{CH}_3\text{NH}_3\text{I}$), First, HI (Sigma-Aldrich) was mixed with Methylamine (CH_3NH_2) in methanol and stirred in ice bath until white crystals were formed. Then, methanol was removed and consequently the solution was filtrated to produce white crystals of $\text{CH}_3\text{NH}_3\text{I}$.

B. Cell Fabrication

The organo-halide PRK solar cell consists of five layers, the layers is the glass/FTO layer acting as the substrate. The glass/FTO substrates were left and cleaned in (isopropyl alcohol) solution for 30 minutes durations to get rid of any residues and contaminants. The ohmmeter was used to determine the conductive side of the glass/FTO substrates. Afterwards, a 150 nm thick TiO_2 was spin-coated on the glass/FTO substrate which act as the electron transport layer (ETL). In this process. The spin coating speed was set to 3000 r.p.m.. Then, a 300 nm thick MAPbI_3 film was deposited on the TiO_2 layer using two-step sequential deposition method [18]. Under a PbI_2/MAI molar ratio of 3:1 condition, the film preparation and deposition was carried out at three different temperatures, as deposited (non- annealed), 100 and 120°C , respectively. After that, a 100 nm thick hole transport layer (HTL) of copper iodide (CuI), were deposited on top of the MAPbI_3 using centrifugation method. Finally, a 80 nm thick Ag layer was thermally evaporated on top of the HTL layer to complete the solar cell device. Thermal evaporation was achieved at a chamber pressure of 10^{-5} mbar. The structure of the completed solar cell device is shown in Figure 3.

C. Characterization of Perovskite Solar Cell

To fabricate a PRK solar cell a 300 nm thick of $\text{Ag/CuI/MAPbI}_3/\text{TiO}_2$ structure was deposited on the glass/FTO

substrate as shown in Figure 3. The efficiency of the fabricated device was measured using light source of AM1.5- illumination [light intensity of 100 mW cm^{-2} at room temperature. The morphology and thickness of PSCs were studied using scanning electron microscopy (SEM) (Model: JSM-7600 F, Jeol). X-ray diffraction (XRD) technique (Model Rigaku ATX-XRD) with Cu K α radiation wavelength of $1.5405 \text{ \AA}$ was used for structural study. UV-Visible Spectrophotometer- [Model Perkin-Elmer lambda 25] was used to investigate the optical properties such as transmittance in the visible & NIR range.

Fig. 3. Schematic of the perovskite device configuration consisting of a glass/TiO₂/Perovskite/CuI/Ag structure.

III. RESULT AND DISCUSSION

A. Analyzing the Film's Structure

Figure 4 shows the effect of three different annealing temperatures on the x-ray diffraction pattern of the MAPbI₃ layer incorporated in the solar cell device as previously mentioned in section 1. B. Results show the presence of small PbI₂ peaks (110) and (220) at 2θ angles of (12.6°) and (37.95°), respectively which have been denoted by asterisk. The other peaks denoted by small circle are related to the MAPI observed at 2θ angles of (13.75°), (20°), (23.4°), (24.3°), (28°), (32°), (35°), (41°), (43°), (50°), (52.3°), (61°), and (68°), respectively. The preferred orientation was observed at 2θ angle of (13.75°) which is related to MAPI. Based on the experimental observations as the annealing temperature increases the intensity of PbI₂ peaks reduces. On the contrary, increase in the annealing temperature resulted in the enhancement of the XRD peak intensity of MAPI. The XRD peaks observed in this study are in agreement with the previous study for cubic MAPI (JCPDS Card No 31-1335) [19].

Fig. 4. The X-ray diffraction (XRD) spectrum of a MAPbI₃ thin film obtained under three different temperature conditions of as-deposited (room temperature or non-annealed), annealed at 100°C and 120°C for 15 minutes in air respectively.

B. Morphological Analysis

Figure 5 shows the SEM images of the MAPbI₃ film obtained with a 3:1 PbI₂/MAI molar ratio at room temperature and annealed after deposition at two different temperatures of 100°C and 120°C , respectively. These results suggest that the annealing significantly changed the morphology of the MAPbI₃ film. The as-deposited (non-annealed) MAPbI₃ film approximately showed a uniform coverage morphology type with small grains with the average size in the range of 225 nm. After annealing at 100°C the increase in the grain size from 150 to 300 nm was observed, however, some voids have been observed in the SEM image of the annealed sample at 100°C . With rising temperature up to 120°C the MAPbI₃ film showed dense pore-free morphology and the average grain size increased to 325 nm.

Fig. 5. The SEM images of MAPbI₃ film with PbI₂/MAI molar ratio of 3:1 obtained, (a) at room temperature (without annealing), (b) annealed at 100 °C and (c) annealed at 120 °C, for 15 minutes durations.

C. Optical Properties

The effect of two different annealing temperature on the optical properties of MAPbI₃ films were studied by measuring spectral transmittance. Figure 6 displays the effect of annealing temperature on the spectral transmittance of the MAPbI₃ film obtained at the condition in which PbI₂/MAI molar ratio was 3:1. Results show the higher transmittance for the non-annealed MAPbI₃ film with cut off wavelength of 775 nm. As the

annealing temperature increased to 100°C and then to 120°C, subsequently, the transmittance of the MAPbI₃ film slightly reduced which indicates the enhancement in optical properties of the film after annealing. Also, after annealing, the cut off wavelengths of the MAPbI₃ film were slightly shifted toward the higher wavelength (lower energy photons).

Fig. 6. Effect of annealing temperature on the transmittance of a typical MAPbI₃ film prepared under a PbI₂/MAI thickness ratio of 3:1.

Figure 7 shows transmittance and reflectance spectra corresponding to typical MAPbI₃ sample free of new phases and in the inset are displayed curves of $(\alpha h\nu)^2$ versus $h\nu$ used to determine the E_g value. It was found that MAPbI₃ film have energy gap of 1.60 eV which is in agreement with the values reported by other authors in the literature [20].

Fig.7. The optical absorption spectra of the non-annealed and annealed MAPbI₃ at two different temperatures of 100 and 120°C, respectively.

D. Electrical Characteristics and Assessment of the Fabricated Glass/FTO/TiO₂/MAPbI₃/CuI/Ag Solar Cell.

Solar cells were fabricated with the structure of Glass/FTO/TiO₂/MAPbI₃/CuI/Ag, where MAPbI₃ is the active layer of the fabricated solar cell. The I-V curves of the fabricated devices were measured under the standard air mass (AM 1.5) with a light source having the irradiance of 100 mW/cm² incident on the active area of 1cm². To assess the performance of Glass/FTO/TiO₂/MAPbI₃/CuI/Ag solar cell, the I-V curves were plotted under light condition and the comparison were made for three devices where the active MAPbI₃ layer was first kept as non-annealed and this layer was then annealed at two different temperatures of 100 and 120°C for 15 minutes in air, respectively and the results is shown in Figure 8.

Fig. 8. I-V curves of the fabricated solar cells with the structure of Glass/FTO/TiO₂/MAPbI₃/CuI/Ag obtained at three conditions of non-annealed (25°C) and annealed at 100 and 120°C, respectively.

Table I shows the values of the corresponding performance parameters {short-circuit current (I_{sc}), open-circuit voltage (V_{oc}), fill factor (FF) and efficiency (η)}. In equation (1) P_m represents the maximum power that can be extracted from the fabricated solar cells and in equation (2) P_{in} and P_{out} respectively represents the power of the incident sunlight and solar cell output power [21]. The influence of the annealing temperature on the performance of the fabricated solar cell in this paper is presented (see Table I). The effect of annealing temperature on the performance of the PRK solar cells has been reported by other authors in the literature [22].

$$FF = \frac{P_m}{V_{oc} I_{sc}} \quad (1)$$

$$\eta(\%) = \frac{P_{out}}{P_{in}} = \frac{I_{sc} V_{oc} FF}{GA} \times 100\% \quad (2)$$

Where A is active area, and G is solar irradiance (1000 Wm⁻² or 100 mWcm⁻²).

TABLE I. EFFECT OF ANNEALING TEMPERATURES ON SOLAR CELL PERFORMANCE

Sample ID No.	Annealing Temperature	I_{sc} (mA)	V_{oc} (V)	FF	η (%)
S ₁	As-deposited (25°C)	20	1.07	0.58	12.4
S ₂	100 °C	22.1	1.1	0.61	14.8
S ₃	120 °C	21.9	1.08	0.60	14.2

As part of this work, we were able to produce a cell with efficiency 14.8 after annealing at 100°C noting that we used TiO₂ and CuI acting as ETL and HTL layers, respectively.

As can be seen from Figure 8 the main reason for the low efficiency is low FF and low short circuit current (I_{sc}), another reason of observing low FF can be due to the high series resistance of the device. The FF also depends on the quality of the solar cell diode, which is affected by the presence of the trap centers in the degradation zone and layer interfaces. Also, it can be due to the low charge transfer at the TiO₂/MAPbI₃ and CuI/MAPbI₃ interfaces. As results of the charge carries recombination at interface states, a high-loss in photocurrent can be observed leading to the lower short-circuit current density as well as lower efficiency. The data reported in Table (1) shows that the annealing temperature of the PRK layer affect the solar cell parameters, thereby affecting the device efficiency. In this research work, the best solar cell parameters were obtained for the layers annealed at 100°C.

E. Stability of the fabricated cell

So far, stability of perovskite solar cells is the most challenge factor which is considered as the main barrier to its commercialization, therefore, the I-V measurement of the Perovskite solar cells were carried out immediately after device fabrication. The I-V measurements were performed under standard test conditions (solar irradiance of 1000W/m², room temperature of 300K, and AM1.5). The degradation of the PSCs device are due to the deterioration [DTR] of the active layer, the DTR of charge transport layers, and the DTR of electrodes. In this work, thermal decomposition [i.e. degradation] occurred at temperature exceeding 100 °C. The Stability, durability, and DTR of the prepared film & the fabricated cells are still under research and will be published later in the next paper.

IV. CONCLUSION

In this paper, we have prepared a thin film with suitable optical properties for solar cell application. The films were prepared by two-step spin coating solution method using precursors of lead iodide synthesized from car battery and methylammonium iodide. The best efficiency of the fabricated solar cells observed in this work was 14.8%. It has been found that CH₃NH₃PbI₃ films synthesized using Pb extracted from car battery, and annealed at 100 °C, showed a better efficiency and performance as compared to other annealing temperatures (non-annealed and 120°C Results of X-ray diffraction, indicated that

the structure of films are affected by different annealing temperatures. The SEM results suggested that the annealing temperature significantly changed the morphology of the MAPbI₃ film. Surface morphology study of the film show the layer with small grains before annealing. Then the grain size increased after annealing at 100 and 120°C. The transmittance of the MAPbI₃ film showed reduction after annealing which means better photon harvesting. Also, the cut-off wavelengths (λ_c) were shifted slightly toward longer wavelength after annealing at 100 and 120°C. The energy band gap value of the MAPbI₃ film was found to be 1.60 eV.
